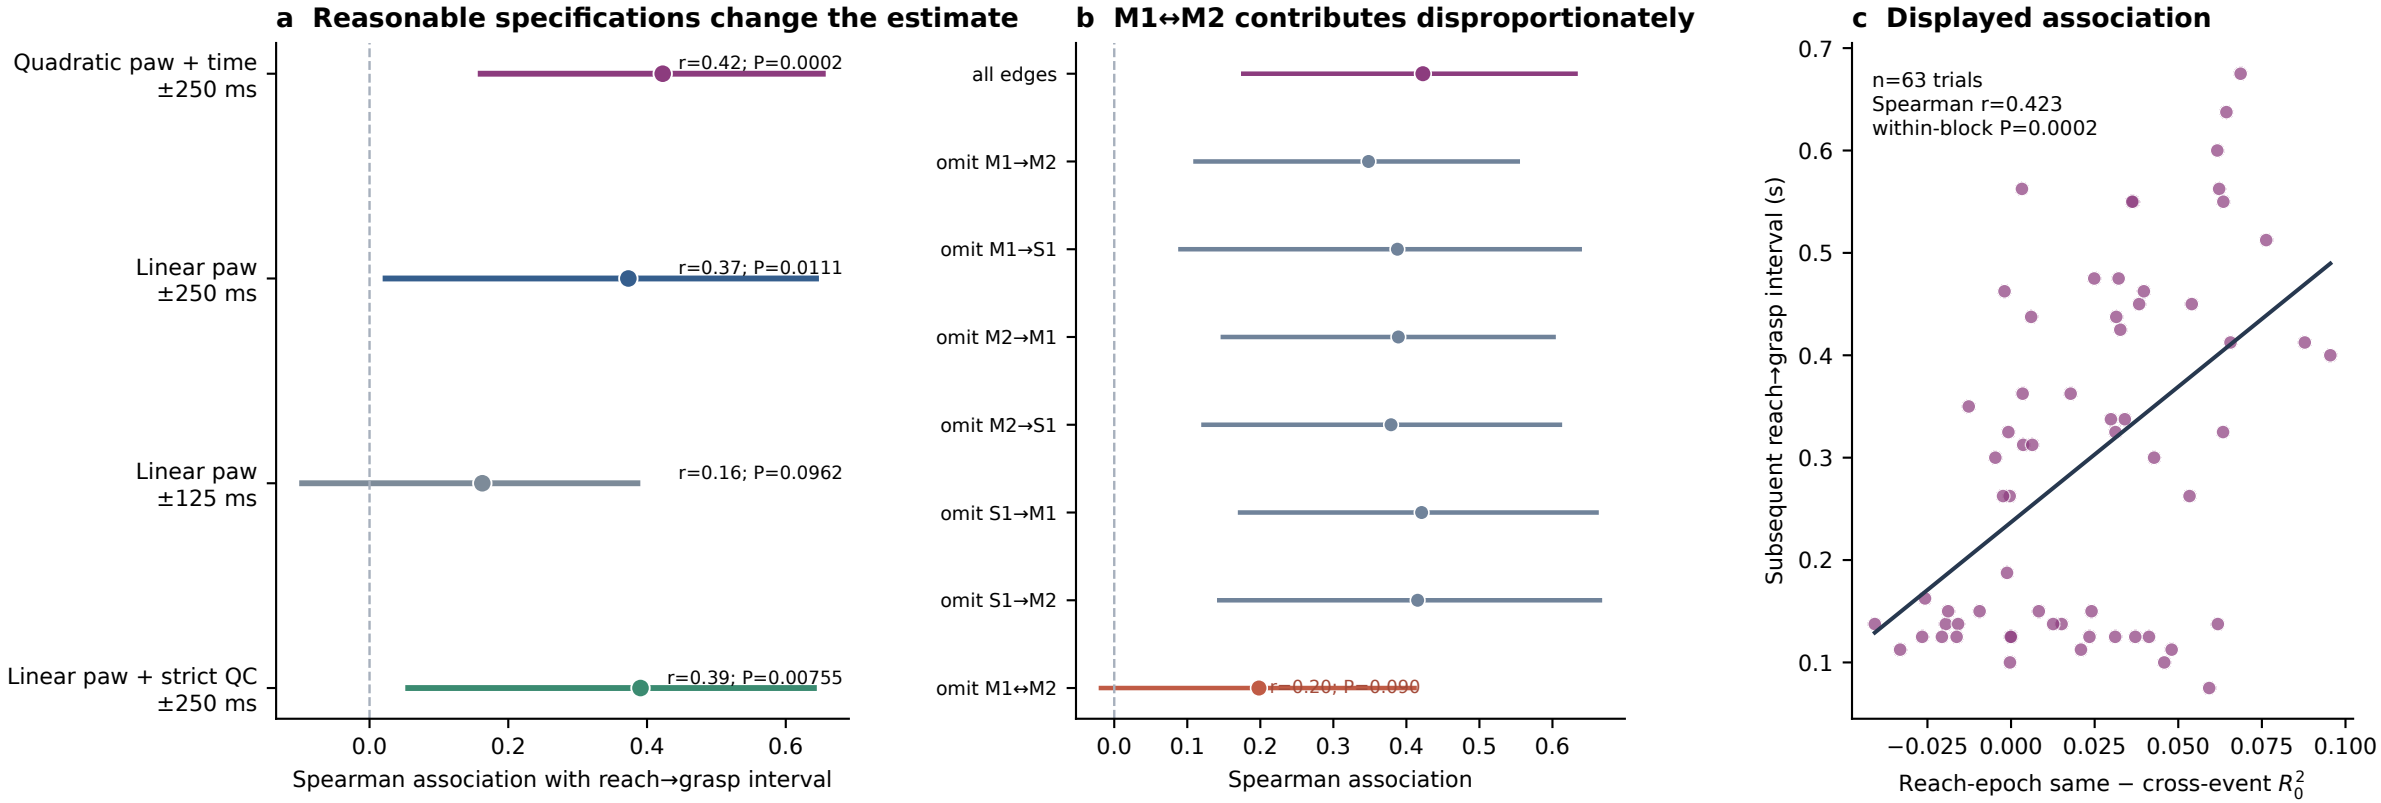
# Extended Data | The reach-latency association is specification-sensitive

All points are complete outer-held-out trials from one mouse-day; this post-hoc audit tests robustness, not biological generality.



Lines: descriptive 95% recording-block bootstrap intervals

Interpretation boundary: the augmented ±250-ms analysis yields a positive within-session association, but the estimate weakens under a narrower ±125-ms window and changes with covariate/QC choices. The relation is post hoc and concentrated partly in M1↔M2 mappings. It may reflect sustained reach-specific organization or event-spacing/window composition. It does not establish behavioral benefit, information flow or causality; independent animals, a locked window and pre-grasp-only analyses are required.
